Received 24 April 2003/Accepted 17 July 2003

**Sleeping sickness, caused by *Trypanosoma brucei* spp., has become resurgent in sub-Saharan Africa. Moreover, there is an alarming increase in treatment failures with melarsoprol, the principal agent used against late-stage sleeping sickness. In *T. brucei*, the uptake of melarsoprol as well as diamidines is thought to be mediated by the P2 aminopurine transporter, and loss of P2 function has been implicated in resistance to these agents. The trypanosomal gene *TbAT1* has been found to encode a P2-type transporter when expressed in yeast. Here we investigate the role of *TbAT1* in drug uptake and drug resistance in *T. brucei* by genetic knockout of *TbAT1*. *Tbat1*-null trypanosomes were deficient in P2-type adenosine transport and lacked adenosine-sensitive transport of pentamidine and melaminophenyl arsenicals. However, the null mutants were only slightly resistant to melaminophenyl arsenicals and pentamidine, while resistance to other diamidines such as diminazene was more pronounced. Nevertheless, the reduction in drug sensitivity might be of clinical significance, since mice infected with *tbat1*-null trypanosomes could not be cured with 2 mg of melarsoprol/kg of body weight for four consecutive days, whereas mice infected with the parental line were all cured by using this protocol. Two additional pentamidine transporters, HAPT1 and LAPT1, were still present in the null mutant, and evidence is presented that HAPT1 may be responsible for the residual uptake of melaminophenyl arsenicals. High-level arsenical resistance therefore appears to involve the loss of more than one transporter.**

Sleeping sickness is caused by *Trypanosoma brucei*, and the disease is endemic throughout tropical Africa. Sleeping sickness is fatal if untreated, and vaccination is impossible due to antigenic variation of the parasites. The main chemotherapeutics for treatment of sleeping sickness are still the melaminophenyl arsenical melarsoprol and the diamidine pentamidine, drugs that were introduced more than 50 years ago. Cross-resistance between melamine-based arsenicals and diamidines has been repeatedly observed in trypanosomes with laboratory-induced drug resistance (14–16, 24, 26). Cellular uptake of both classes of trypanocide has been shown to occur via the P2 adenosine/adenine transport activity in *T. brucei* bloodstream forms, and loss of P2 has been implicated in drug resistance (5, 6). Subsequently, a trypanosome gene (*TbAT1*) that exhibited P2-like transport activity when expressed in yeast was cloned (19). The function of *TbAT1* in trypanosomes, however, remained to be investigated.

No clear correlation was found between mutations in *TbAT1* and relapses after melarsoprol treatment in sleeping sickness patients in Uganda (22), and *T. brucei* isolated from melarsoprol-refractory patients did not show high levels of in vitro arsenical resistance (4, 21). [<sup>3</sup>H]pentamidine transport in *T. brucei* was only partially blocked by adenosine (5, 7, 11), and

adenosine transport in *Saccharomyces cerevisiae* expressing *TbAT1* was not inhibited by pentamidine (19). The situation is further complicated by the fact that nucleoside transporters comprise a multigene family in *T. brucei* (28). Thus, a model whereby the loss of a single transporter (*TbAT1*) could mediate cross-resistance to all diamidines and melamine-based arsenicals appears overly simplistic.

Meanwhile, the problem of drug resistance in *T. brucei* appears to be increasing in the field. Sleeping sickness has recently become resurgent in sub-Saharan Africa, and the emergence of drug resistance is hindering efforts to control the disease. Melarsoprol treatment failures have reached alarming levels in several foci (4). In addition, resistance to the diamidine diminazene aceturate has also been reported from multiple foci (17, 23). Pentamidine resistance, in contrast, has so far not been reported from the field. The understanding of resistance mechanisms in bloodstream-form trypanosomes is crucial to circumventing existing resistance problems and avoiding the emergence of resistance to the next generation of drugs.

To investigate whether *TbAT1* alone contributes to P2 activity in *Trypanosoma brucei brucei*, we have constructed a *TbAT1* knockout clone by targeted gene replacement. We have further used this null mutant to resolve the role of *TbAT1* in the uptake of, and resistance to, the diamidine and melaminophenyl arsenical classes of drugs.

### MATERIALS AND METHODS

**Propagation of trypanosomes.** Bloodstream-form *T. brucei brucei* strain 427 (s427; also known as MiTat 1.2/221 or BS 221) parasites were used to construct the *TbAT1*<sup>-/-</sup> line. They were cultured in minimal essential medium modified

† Present address: Livestock Health Research Institute, Tororo, Uganda.

according to the work of Baltz et al. (1), supplemented with 5% fetal bovine serum. For transport experiments, adult female Wistar rats were infected by intraperitoneal injection. At peak parasitemia, blood was collected by cardiac puncture under terminal anesthesia. The parasites were isolated by using a DE52 (Whatman, Maidstone, United Kingdom) anion-exchange column (18) and washed twice in assay buffer (33 mM HEPES, 98 mM NaCl, 4.6 mM KCl, 0.55 mM CaCl<sub>2</sub>, 0.07 mM MgSO<sub>4</sub>, 5.8 mM NaH<sub>2</sub>PO<sub>4</sub>, 0.3 mM MgCl<sub>2</sub>, 23 mM NaHCO<sub>3</sub>, 14 mM glucose [pH 7.3]).

**Constructs for the *TbAT1* gene deletion.** *TbAT1* alleles were replaced sequentially with resistance markers for the antibiotics neomycin and puromycin. Flanking sequences upstream (700 bp) and downstream (300 bp) of the *TbAT1* open reading frame were amplified by PCR and cloned into plasmids so that they flanked *NEO* or *PAC* genes. The resulting deletion constructs were released from plasmid DNA by restriction digestion, purified by phenol extraction, and resuspended to 0.2 µg/µl in water.

**Transfection of trypanosomes.** Bloodstream-form trypanosomes (s427) were cultured to a density of  $2 \times 10^6$  ml<sup>-1</sup>. A total of 10<sup>8</sup> cells were washed in 15 ml of ZMG buffer (132 mM NaCl, 8 mM KCl, 8 mM Na<sub>2</sub>HPO<sub>4</sub>, 1.5 mM KH<sub>2</sub>PO<sub>4</sub>, 0.775 mM magnesium acetate, 0.063 mM calcium acetate [pH 7.5]) and resuspended in 450 µl of ZMG and 50 µl of deletion construct DNA solution. The cell suspension was electroporated by using a Bio-Rad GenePulser at 1.5 kV, 25 µF, and 200 ΩF and was transferred to culture medium. Drug selection was applied after 24 h, and trypanosomes were cloned in vitro after 7 days of selection. Neomycin (1.5 µg/ml) was used for the first-round knockout, and neomycin plus puromycin (0.15 µg/ml) was used for the second-round knockout.

**Southern blotting.** Genomic DNAs of the wild-type s427, two first-round knockout clones, and two second-round derivatives of each were digested with *EcoRI* and *NdeI*. Southern blotting was performed by standard protocols. *TbAT1* and neomycin and puromycin resistance genes were labeled by using the DIG system (Roche Diagnostics, Basel, Switzerland).

**Transport assays.** Transport assays for [<sup>3</sup>H]adenosine (NEN) and [<sup>3</sup>H]pentamidine (Amersham) were performed exactly as described previously (7, 31) by using a rapid oil stop protocol. Briefly, trypanosomes were harvested, washed twice with the assay buffer, and resuspended at 10<sup>8</sup> cells/ml. Cells were then incubated with the radioligand in the presence or absence of a competitive inhibitor and were spun through oil (for 30 s at 12,000 × g) after a predetermined time as indicated in Results. Radioactivity in the cell pellet was determined, after solubilization in 2% sodium dodecyl sulfate, by liquid scintillation counting.

**In vitro drug sensitivity assays.** In vitro drug sensitivity was determined by using the Alamar Blue assay (25). Trypanosomes (10<sup>4</sup>) were exposed to doubling dilutions of drugs for 2 days at 37°C before Alamar Blue reagent (Bio-SOURCE, Camarillo, Calif.) was added. After a further 24 h of incubation, fluorescence was determined in a fluorimeter (Perkin-Elmer LS55B). Fifty percent inhibitory concentrations (IC<sub>50</sub>) were determined by nonlinear regression using the Prism (GraphPad) software package. For in vitro lysis assays (14), trypanosomes were exposed to 10 µM melarsen oxide or cymelarsan in the presence or absence of potential inhibitors of drug uptake. Lysis was monitored spectrophotometrically by determination of absorbance at 750 nm at 60-s intervals.

**In vivo experiments.** Twenty-eight NMRI outbred mice (young adults, female, weighing around 25 g) were inoculated intraperitoneally with 10<sup>5</sup> trypanosomes. Seven groups of four mice each were infected as follows: groups A, D, and G received wild-type s427, groups B and E received knockout clone 12, and groups C and F received knockout clone 21. Three days postinfection, all mice showed strong parasitemia and were treated with melarsoprol at 2 mg/kg of body weight<sup>-1</sup> (groups A, B, and C) or 10 mg/kg<sup>-1</sup> (groups D, E, and F) for four consecutive days. Group G comprised untreated controls. Melarsoprol (3.6% solution in propylene glycol) was diluted with phosphate-buffered saline to 60 and 300 µg/100 µl, and mice were treated by intraperitoneal injection of 100 µl for the 2- and 10-mg/kg<sup>-1</sup> doses, respectively. The mice were monitored twice a week for parasitemia by examination of smears of tail blood.

**Data analysis.** All experiments were performed in triplicate or more. Kinetic data, given as means and standard errors, were determined in at least three independent experiments and calculated by nonlinear regression using the Prism (GraphPad) software package from a minimum of 8 points over the relevant range. All uptake data are presented as “mediated uptake,” defined as total uptake minus diffusion. Diffusion is taken to be uptake in the presence of saturating concentrations of unlabeled permeant.

## RESULTS

**Construction of *tbat1*-null mutants.** The *TbAT1* gene was replaced in two steps, by sequential transformation of *T. b.*

*brucei* s427 bloodstream forms with constructs containing the neomycin and puromycin resistance markers. To investigate whether the constructs had correctly integrated and replaced *TbAT1*, genomic DNAs from several first- and second-round antibiotic-resistant transformant clones, as well as from the parental wild-type trypanosomes, were analyzed by Southern blotting. Hybridization with probes for *TbAT1* or resistance marker genes revealed heterozygous and homozygous *tbat1*-null clones as expected (data not shown).

The *tbat1*<sup>-/-</sup> trypanosomes did not exhibit any obvious differences in morphology or motility from the wild-type parent strain s427. The population doubling time in culture was not significantly different, remaining at around 8 h for both strains. *tbat1*<sup>-/-</sup> trypanosomes remained fully infective to mice (data not shown). Thus, *TbAT1* is not essential for cell survival, cell-cycle progression, or the course of infection in rodents, presumably because of the presence of additional purine transporters in bloodstream-form trypanosomes (6, 9, 10, 13).

**Adenosine transport in *tbat1*-null mutants.** *T. b. brucei* bloodstream forms possess two adenosine transporter activities, P1 and P2, which are selectively inhibited by inosine and adenine, respectively (6, 10). The underlying genes encoding each activity have not been determined conclusively so far. In *tbat1*-null trypanosomes, uptake of 0.1 µM [<sup>3</sup>H]adenosine was completely inhibited by inosine (Fig. 1), with an IC<sub>50</sub> of 0.74 ± 0.09 µM, very similar to values reported previously for the P1 activity (6, 10, 12). In contrast, as much as 100 µM adenine failed to inhibit [<sup>3</sup>H]adenosine transport (Fig. 1). This result indicates that the P2 adenosine transport activity has been completely deleted in the *tbat1*-null mutant, as adenosine transport mediated by P2 has been shown to be sensitive to adenine with a K<sub>i</sub> of ~0.2 µM (6, 10).

**Pentamidine transport in *tbat1*-null mutants.** [<sup>3</sup>H]pentamidine transport in *tbat1*-null bloodstream forms was not inhibited by as much as 1 mM adenosine (Fig. 2). This is in marked contrast with transport in wild-type *T. b. brucei*, where an adenosine-sensitive pentamidine transporter (ASPT1) is responsible for about 50% of total pentamidine uptake (7, 11). The absence of an adenosine-sensitive pentamidine flux in the *tbat1*-null mutants clearly demonstrates that *TbAT1* encodes the previously described ASPT1 activity (7, 11). The reported failure of pentamidine to inhibit adenosine uptake by *TbAT1* expressed in yeast (19, 20) raises the question as to whether auxiliary factors, present in the trypanosome plasma membrane, are required to confer diamidine transport by *TbAT1*.

Increasing concentrations of unlabeled pentamidine inhibited uptake of 15 nM [<sup>3</sup>H]pentamidine in a biphasic manner (Fig. 2), revealing the presence of a high-affinity and a low-affinity component of pentamidine transport, termed HAPT1 and LAPT1, respectively (7). At 15 nM, [<sup>3</sup>H]pentamidine transport by HAPT1 and LAPT1 in *tbat1*-null trypanosomes was inhibited by unlabeled pentamidine, with IC<sub>50</sub> of 29 ± 8 nM and 50 ± 17 µM (*n* = 3), respectively, consistent with values reported previously for wild-type trypanosomes (7, 11). HAPT1 and LAPT1 can be further distinguished by the fact that only HAPT1 is inhibited by propamidine (7). Propamidine inhibited the high-affinity uptake of [<sup>3</sup>H]pentamidine in *tbat1*-null trypanosomes with an IC<sub>50</sub> of 13 ± 3 µM (*n* = 4) (Fig. 2) but had no effect on the low-affinity uptake phase.

FIG. 1. Uptake of [ $^3\text{H}$ ]adenosine by the *that1*-null mutant. Uptake of 20 nM [ $^3\text{H}$ ]adenosine was inhibited by inosine (filled squares) with an  $\text{IC}_{50}$  of  $1.1 \pm 0.1 \mu\text{M}$ . Adenine failed to inhibit [ $^3\text{H}$ ]adenosine at concentrations as high as 100  $\mu\text{M}$  when it was added alone (open squares). The inhibition induced by 1 mM adenine is attributable to a low-affinity inhibition of P1.

**Drug resistance profiles of *that1*-null mutants.** In order to test the hypothesis that loss of *TbAT1* causes drug resistance, *that1*-null and wild type trypanosomes were cultured in vitro in the presence of serial dilutions of trypanocidal diamidines and melaminophenyl arsenicals. The assays for both strains were performed in parallel in order to minimize the influence of interassay variation. As summarized in Table 1, *that1*-null mutants indeed showed decreased drug sensitivity. Resistance to melaminophenyl arsenicals (melarsoprol, melarsen oxide,

cymelarsan), however, was consistently only two- to threefold relative to the *s427* parent strain. Pentamidine resistance was in the same range. In contrast, *that1*-null mutants showed markedly higher levels of resistance to stilbamidine, propamidine, and in particular diminazene aceturate (Berenil).

The low levels of resistance to melarsoprol in the null mutant were confirmed in vivo. Mice infected with *s427* were all cured after treatment with 2 or 10 mg of melarsoprol/kg for four consecutive days. In contrast, all mice infected with one of

FIG. 2. Uptake of [ $^3\text{H}$ ]pentamidine by the *that1*-null mutant. The uptake of 15 nM [ $^3\text{H}$ ]pentamidine was unaffected by as much as 1 mM adenosine (filled circles) but was inhibited to a maximum of 64% by propamidine (open squares), with an  $\text{IC}_{50}$  of 6.5  $\mu\text{M}$ . When increasing amounts of unlabeled pentamidine (filled squares) were added, [ $^3\text{H}$ ]pentamidine uptake was inhibited in a biphasic manner ( $P < 0.0001$  by the  $F$  test), with the high-affinity component ( $\text{IC}_{50} = 25.1 \text{ nM}$ ) contributing 62% of total [ $^3\text{H}$ ] pentamidine transport. The  $\text{IC}_{50}$  of the low-affinity component was 19.5  $\mu\text{M}$  for this experiment.

TABLE 1. Drug resistance phenotype of the *tbat1*-null mutant compared to the parental wild-type strain

Drug	IC <sub>50</sub> <sup>a</sup> (ng/ml)		Resistance factor
	Wild type	<i>Tbat1</i> <sup>-/-</sup> mutant	
Melarsoprol	21 ± 3	49 ± 9	2.3
Melarsen oxide	3.7 ± 0.1	11 ± 0.1	3.0
Cymelarsan	6.1 ± 1	12 ± 3	2.0
Pentamidine	5.1 ± 2	12 ± 3	2.4
Diminazene	120 ± 30	2,300 ± 500	19
Propamidine	67 ± 7	750 ± 20	11
Stilbamidine	680 ± 70	5,000 ± 1,300	7.4

<sup>a</sup> IC<sub>50</sub> were determined in vitro by using the Alamar Blue assay. Values are means from at least three independent experiments ± standard errors.

the two knockout clones relapsed after treatment with 2 mg of melarsoprol/kg and died due to parasitemia by day 20 post-treatment. The 10-mg/kg dosage of melarsoprol still effectively cured mice infected with *tbat1*-null trypanosomes.

**Additional pathways for arsenical uptake.** The comparably small reduction of melarsoprol sensitivity in *tbat1*-null trypanosomes suggests the presence of further, TbAT1-independent pathways for drug uptake. Transport of melaminophenyl arsenicals cannot be studied directly for lack of a radiotracer, but the lytic effect of these compounds on trypanosomes in vitro can serve as a bioassay for arsenical uptake (14, 29, 33). Treatment with 10 μM melarsen oxide or cymelarsan induced rapid lysis of wild-type s427 bloodstream forms, with onset typically occurring at 15 to 30 min and complete lysis within 1 h (Fig. 3a). Simultaneous incubation with adenosine, adenine, or pentamidine prevented lysis, while inosine, guanosine or hypoxanthine had no effect (Fig. 3a and data not shown). For the *tbat1*-null mutant, however, the onset of melaminophenyl arsenical-induced lysis was significantly delayed (typically to 4 h) and lysis was much slower (Fig. 3b). This is consistent with

*TbAT1* representing the transporter responsible for the fast component of melaminophenyl arsenical uptake.

Adenosine and other purines had no effect on the slow lysis of *tbat1*-null cells by melaminophenyl arsenicals (data not shown), but lysis was fully prevented by diamidines, most potently by pentamidine. Fifty percent effective concentrations were 30 nM for pentamidine, 300 nM for propamidine, and approximately 10 μM for stilbamidine (Fig. 3b). To investigate whether this counteracting effect of diamidines was caused by competition for a common transporter or occurred at the site of arsenical action, phenylarsine oxide was used as an arsenical trypanocide that diffuses rapidly across the cell membrane and therefore does not rely on transporters for its trypanocidal action (6, 29). Treatment of *tbat1*-null mutants with 0.5 μM phenylarsine oxide caused rapid lysis (Fig. 3c, trace b). Neither adenosine (10 mM), hypoxanthine (4 mM), pentamidine, stilbamidine, nor propamidine (the last three at 100 μM) prevented lysis; only a very high concentration of pentamidine (1 mM) did have some effect (Fig. 3c). The most likely explanation for the counteracting effects of diamidines on the slow cymelarsan-induced lysis of *tbat1*-null trypanosomes is therefore the inhibition of a transport mechanism. Furthermore, this transporter is likely to be HAPT1, as half-maximal diamidine concentrations for inhibition of cymelarsan-induced lysis correlate well with *K<sub>i</sub>* values of the respective diamidines for HAPT1 (7). The observation that melarsen oxide exhibits low affinity for HAPT1 (IC<sub>50</sub>, ~250 μM [data not shown]) is consistent with this hypothesis.

## DISCUSSION

Since Carter and Fairlamb showed that adenosine and adenine protect *T. b. brucei* from melarsen-induced lysis in vitro (6), several studies have pointed to a role for the P2 transport

FIG. 3. In vitro sensitivities of bloodstream-form trypanosomes to arsenical trypanocides. (a) Wild-type *T. b. brucei* s427 parasites were incubated with or without 10 μM melarsen oxide in the presence of potential inhibitors. Traces: a, control (no arsenical); b, melarsen oxide only; c, melarsen oxide plus 4 mM adenosine; d, melarsen oxide plus 1 mM pentamidine; e, melarsen oxide plus 4 mM hypoxanthine. (b) Cells of the *tbat1*-null mutant were incubated with or without 10 μM cymelarsan. Traces: a, control (no arsenical); b, cymelarsan only; c, cymelarsan plus 0.1 μM pentamidine; d, cymelarsan plus 0.03 μM pentamidine; e, cymelarsan plus 0.01 μM pentamidine; f, cymelarsan plus 10 μM stilbamidine; g, cymelarsan plus 1 μM propamidine; h, cymelarsan plus 0.3 μM propamidine; i, cymelarsan plus 0.1 μM propamidine. (c) Cells of the *tbat1*-null mutant were incubated with or without 0.5 μM phenylarsine oxide. Traces: a, control (no arsenical); b, phenylarsine oxide only; c, phenylarsine oxide plus 10 mM adenosine; d, phenylarsine oxide plus 4 mM hypoxanthine; e, phenylarsine oxide plus 1 mM pentamidine; f, phenylarsine oxide plus 100 μM pentamidine; g, phenylarsine oxide plus 100 μM propamidine; h, phenylarsine oxide plus 100 μM stilbamidine. Arrow indicates time of phenylarsine oxide addition.

activity in the resistance of African trypanosomes to both melaminophenyl arsenicals and diamidines (2, 5, 27, 29, 30). A *T. b. brucei* gene, *TbAT1*, was found to encode an adenine-sensitive adenosine transporter when expressed in yeast (19), but formal proof that *TbAT1* encodes the P2 activity in trypanosomes has awaited the gene deletion study presented here. The total absence of P2-type transport in *tbat1*-null bloodstream-form trypanosomes proves that TbAT1 is the P2 transporter. We found that loss of *TbAT1* did indeed reduce the sensitivity of trypanosomes to melaminophenyl arsenicals, but only by factors of 2 to 3 (Table 1). However, even such a limited loss of sensitivity could be significant in a clinical setting, since the drug levels in the cerebrospinal fluid of melarsoprol-treated patients are at the threshold of those needed to kill trypanosomes (reviewed in reference (8)). A small reduction in drug sensitivity could therefore lead to survival of some parasites in the central nervous system or other extravascular sites and cause clinical relapse in an increased percentage of patients. This model is in agreement with the lack of high-level arsenical resistance in clinical isolates from melarsoprol-refractory patients (4, 21).

The P2 transporter, when analyzed in trypanosomes, displays high affinity for several trypanocidal diamidines, including pentamidine, as judged by their ability to inhibit adenosine uptake (2, 5, 7, 10). [<sup>3</sup>H]pentamidine transport, however, was only partially blocked by adenosine in *T. brucei* (5). Here we show that adenosine-sensitive pentamidine transport (ASPT1) is completely lost in *tbat1*-null trypanosomes. Nevertheless, *tbat1*-null trypanosomes are only about twofold more resistant to pentamidine than wild-type trypanosomes, while resistance to other diamidines such as diminazene is much more pronounced. This can be explained by the presence of two additional, adenosine-insensitive transporters specific for pentamidine: the high-affinity pentamidine transporter HAPT1 and the low-affinity pentamidine transporter LAPT1 (7). We show here that both activities are retained in the *tbat1*-null mutants. The veterinary trypanocide diminazene, though structurally related to pentamidine, is not an effective substrate for HAPT1 or LAPT1 (7, 11) and may not enter trypanosomes, to an appreciable extent, by routes other than *TbAT1*. This may explain why trypanosomes have not developed resistance to pentamidine in the field while resistance to diminazene is much more common (17, 23), although both drugs have been used extensively over several decades (3, 32).

Some laboratory strains of *T. brucei*, selected for arsenical resistance by prolonged exposure to subcurative doses, have been shown to be deficient in P2 activity, but, unlike the *tbat1*-null trypanosomes, exhibit high levels of resistance to melaminophenyl arsenicals (14, 29). This indicates that besides loss of TbAT1, further events are required for high-level arsenical resistance. At least part of this is likely to occur at the level of plasma membrane transport, as the in vitro lysis assays showed that the *tbat1*-null trypanosomes remained fully sensitive to phenylarsine oxide, which is lipophilic and diffuses across membranes without the need for transporters (6, 29). This arsenical contains the same trivalent toxophore as melarsen oxide, differing only in the presence of an extra melamine haptophore in the latter arsenical at the *para* position of the phenyl ring. It is therefore probable that the cause for high-level melaminophenyl arsenical resistance, like that for

low-level resistance, is associated with the uptake of the drug over the plasma membrane. The in vitro lysis assays with *tbat1*-null trypanosomes also revealed a slow, adenosine-insensitive uptake of melaminophenyl arsenicals. Inhibitor analysis indicated that this transporter could be HAPT1. These data need to be interpreted with some caution, since the possibility that these diamidines inhibit an additional transport mechanism with affinities similar to those they exhibit for HAPT1 cannot be discounted. In this scenario, pentamidine might well be an inhibitor rather than a permeant for any such putative transport protein for melaminophenyl arsenicals, as there is currently no evidence of pentamidine transporters in addition to HAPT1, LAPT1, and TbAT1 (7, 11). However, if HAPT1 and TbAT1 do both mediate cellular uptake of melaminophenyl arsenicals, loss of both may be necessary for high-level drug resistance.

In conclusion, genetic knockout of *TbAT1* in *T. b. brucei* bloodstream forms revealed a major role for TbAT1 in the uptake of clinically important trypanocides. Loss of TbAT1 activity appears to cause loss of sensitivity to melaminophenyl arsenicals and diamidines and is an obligatory component of high-level resistance. *Tbat1*-null trypanosomes further allowed the characterization and possible identification of additional drug transport activities. The exploitation of alternative pathways for drug uptake will be crucial for the development of new-generation trypanocides that do not share cross-resistance with P2 substrates.
